## Abstract

Prominent theories highlight the importance of bodily perception for self-consciousness, but it is currently not known whether this is based on interoceptive or exteroceptive signals or on integrated signals from these anatomically distinct systems. Here, we combined both types of signals, providing participants with visual exteroceptive information about their heartbeat: a real-time video image of a periodically illuminated silhouette outlining the participant's ("virtual") body and flashing in synchrony with their heartbeat. We investigated whether these "cardio-visual" signals could modulate bodily self-consciousness and tactile perception, and report two main findings. First, synchronous cardio-visual signals increased self-identification with and self-location towards the virtual body, and, secondly, altered the perception of tactile stimuli applied to participants' backs, so that touch was mislocalized towards the virtual body. We argue that the integration of signals from the inside and the outside of the human body is a fundamental neurobiological process underlying self-consciousness.

## Introduction

Neurological, neuroimaging, and psychological data have highlighted the importance of bodily perception for a neurobiological model of the self and subjectivity. Inspired by early neurological research on the body schema (Head & Holmes, 1911; Schilder, 1935), recent clinical research described alterations of the self in cases of disturbed multisensory integration (Blanke, Landis, Spinelli, & Seeck, 2004; Brugger, Regrad, & Landis, 1997; Heydrich, Dieguez, Grunwald, Seeck, & Blanke, 2010; Vallar & Ronchi, 2009). These clinical insights inspired the use of multisensory conflicts to systematically alter the perception of the body and self (Blakemore, Wolpert, & Frith, 1998; Botvinick & Cohen, 1998; Dieguez, Mercier, Newby, & Blanke, 2009; Fournieret & Jeannerod, 1998; Lenggenhager, Tadi, Metzinger, & Blanke, 2007).

Alterations of the self and the generation of illusory own body perceptions through multisensory conflicts have mostly affected isolated body parts such as fingers (Dieguez et al., 2009), hands (Botvinick & Cohen, 1998), arms (Fournieret & Jeannerod, 1998), or the face (Sforza, Bufalari, Haggard, & Aglioti, 2010), but can also induce changes in the perception of the entire body (Ehrsson, 2007; Lenggenhager et al., 2007). In one such illusion (Lenggenhager et al., 2007) participants viewed their own body from behind through a head mounted display while their back was stroked. With synchronous stroking, participants self-identified with the 'virtual' body and mislocalized their self towards where the virtual body was seen.

These studies on the bodily self manipulated only exteroceptive sensory sources of information about the body (i.e. vision and touch). However, prominent evidence has been put forward that the brain's representations of internal bodily states (e.g. the heartbeat

1  
2  
3 (Critchley, Wiens, Rotshtein, Ohman, & Dolan, 2004)) are equally important or even more  
4  
5 important for the self (A. D. Craig, 2002; Damasio, 2000). Although recent patient work  
6  
7 suggests that exteroceptive and interoceptive signals can be integrated (in visceral  
8  
9 perception (Khalsa, Rudrauf, Feinstein, & Tranel, 2009)), until now, no one has investigated  
10  
11 how these two signals might interact to jointly affect bodily self-consciousness. This is  
12  
13 surprising given what is known about the convergence of visceral and somatosensory signals  
14  
15 in single neurons in the spinal cord, brain stem, and thalamus (Foreman, Blair, & Weber,  
16  
17 1984; Takahashi & Yokota, 1983) and clinical data from patients with coronary heart disease  
18  
19 and referred pain (Ruch, 1965).  
20  
21  
22  
23  
24

25 We therefore developed an experimental setup that investigated whether a conflict  
26  
27 between an interoceptive signal (the heartbeat) and an exteroceptive (visual) signal would  
28  
29 modulate bodily self-consciousness and whether this cardio-visual conflict would also alter  
30  
31 exteroception (tactile perception). We thus presented cardio-visual illumination of the  
32  
33 virtual body so that a flashing silhouette was either temporally synchronous or asynchronous  
34  
35 with respect to the subject's heartbeats. We predicted that participants would feel greater  
36  
37 self-identification with the virtual body, would self-locate more towards the virtual body,  
38  
39 and that tactile stimuli would be mislocalised towards the virtual body more in the  
40  
41 synchronous than the asynchronous condition. Our data show that synchronous cardio-  
42  
43 visual signals increased self-identification with and self-location towards the virtual body and  
44  
45 also altered the perception of tactile stimuli (relative to the asynchronous condition).

## Methods

### Participants

A total of 17 healthy right-handed participants took part (9 females, mean age 26.7±5.6 years). All participants had no previous experience with the task or related experimental paradigms. All participants had normal or corrected to normal vision and had no history of neurological or psychiatric conditions. All participants gave written informed consent and were compensated for their participation. The study protocol was approved by the local ethics research committee – La Commission d'éthique de la recherche Clinique de la Faculté de Biologie et de Médecine – at the University of Lausanne, Switzerland and was performed in accordance with the ethical standards laid down in the Declaration of Helsinki.

### Materials and procedure

#### *Setup, electrocardiogram (ECG), signal analysis*

The present protocol adapted an experimental setup that has been used previously to study bodily self-consciousness and visuo-tactile integration (Aspell, Lenggenhager, & Blanke, 2009; Ehrsson, 2007; Lenggenhager et al., 2007). Participants stood with their backs facing a video camera placed 2 meters behind. The video, showing the participant's body (virtual body) was projected in the body conditions in real time onto a head mounted display (HMD), see Figure 1. While filming the video we also recorded the participant's ECG throughout the entire experiment. Raw data (ECG) were acquired with the BioSemi Active II™ system (Biosemi, The Netherlands) at a sampling rate of 2048Hz. In-house software was developed to detect, in real time, the peak of each R-wave from the recorded ECG data and to trigger an additional visual stimulus (e.g. a flashing outline surrounding the participant's

1  
2  
3 virtual body) that flashed on and off synchronously or asynchronously with respect to the  
4  
5 participant's heartbeat (for further details please refer to the Supplementary Material and  
6  
7 Supplementary Figure S1). There were 4 different blocks corresponding to 4 different  
8  
9 conditions: (1) Body with flashing outline synchronous with the heartbeat (body  
10  
11 synchronous, BS); (2) Body with flashing outline asynchronous with the heartbeat (body  
12  
13 asynchronous, BAS); (3) Object with flashing outline synchronous with the heartbeat (object  
14  
15 synchronous, OS); (4) Object with flashing outline asynchronous with the heartbeat (object  
16  
17 asynchronous, OAS).  
18  
19  
20  
21  
22  
23

#### 24 *Self-identification and self-location*

25  
26 Participants' subjective responses were assessed at the end of each block by an  
27  
28 eleven-item questionnaire adapted from (Lenggenhager et al., 2007); see Table 1) that  
29  
30 allowed us to quantify self-identification with the virtual body. The questions were randomly  
31  
32 ordered and rated on a 7-point Likert scale between -3 to 3, in which -3 indicated complete  
33  
34 disagreement and +3 complete agreement.  
35  
36  
37

38  
39 At the end of each block (duration ~6 min) we measured self location as described  
40  
41 previously (Lenggenhager et al., 2007). To do this we first passively displaced the participant  
42  
43 backwards by 1.5 meters (the experimenter gently guided the participants - who had their  
44  
45 eyes closed - while they took very small steps backwards). They were then asked to walk  
46  
47 back to their initial position (while keeping their eyes closed) with normal sized steps. The  
48  
49 distance between the original position and the position estimated by the participant (drift)  
50  
51 was measured.

### *Tactile perception - the cross modal congruency effect*

To measure the effect of cardio-visual stimulation on tactile perception, we adapted our previous setup and paradigm that allowed us to measure visuo-tactile CCEs (Aspell et al., 2009); for further details please refer to the Supplementary Material). Participants were instructed to keep their eyes open, to fixate a location in the middle of their backs as viewed via the HMD and to stand still while waiting for the first vibro-tactile and LED stimuli (presented one minute after the start of the trial). For the measurement of the visuo-tactile CCE, participants had to indicate with their right hand, by pressing one of two buttons as fast as possible whether they felt a vibration at the top (an upper device) or at the bottom (a lower device) of their backs (regardless of side), while trying to ignore the light flashes. Four conditions (with 25 trials each) were thus presented, which differed in the relative locations of the target vibrator and the distractor LED: (1) same side, congruent elevation; (2) same side, incongruent elevation; (3) different side, congruent elevation; (4) and different side, incongruent elevation. We analyzed reaction times (RTs) and accuracies in each condition.

### **Statistical analysis**

In order to assess the illusion strength we first compared the subjective ratings in the illusion questions (question 1-3) with the ratings in the control question (question 4-11) in the 4 experimental conditions using a two-tailed 3-way repeated-measures ANOVA with within-subject factors body (body/object), synchrony (synchronous/asynchronous) and question type (illusion/control) as described previously (Morgan et al., 2011; Palluel, Aspell, Lavanchy, & Blanke, 2012; Slater, Perez-Marcos, Ehrsson, & Sanchez-Vives, 2008). In order to follow up on the results of the ANOVA, we carried out planned-comparisons using a paired t-test. Based on previous work using visuo-tactile stimulation (Botvinick & Cohen, 1998; Ionta

1  
2  
3 et al., 2011; Lenggenhager et al., 2007), we postulated the *a priori* hypothesis of higher  
4  
5 subjective ratings in the illusion questions in the BS condition as compared to the BAS  
6  
7 condition and no such difference for the object conditions (OS and OAS) and the control  
8  
9 questions. The significance level (alpha) used was adjusted for multiple comparisons using  
10  
11 the Bonferroni method ( $p=0.0125$ ).  
12  
13

14  
15 In a second step we focused in more detail on the differences of the ratings from the  
16  
17 illusion questions (in particular question 3 “I felt as if the virtual body/object was my body”),  
18  
19 performing planned-comparisons between BS-BAS, OS-OAS, BS-OS and BAS-OAS using a  
20  
21 paired t-test. Again, we postulated the *a priori* hypothesis of higher ratings in the BS  
22  
23 condition as compared to the BAS condition and of generally higher ratings in the body  
24  
25 conditions as compared to the object conditions (contrasts BS-OS and BAS-OAS) but no  
26  
27 significant difference between the object conditions (OS and OAS). Moreover, in order to  
28  
29 make sure that the observed effects are not due to the subjects being aware of the  
30  
31 manipulation, question 8 (“It seemed as if the flashing semi-transparent template was my  
32  
33 heartbeat”) was analyzed using the same contrasts. Accordingly, the significance level used  
34  
35 (alpha) was adjusted using the Bonferroni method ( $p=0.003$ ).  
36  
37  
38  
39

40  
41 The drift (self-location) measures (calculated relative to the initial position = 0) were  
42  
43 analyzed using repeated measures analyses of variance (ANOVA) with the factors body  
44  
45 (body/object) and synchrony (synchronous/asynchronous). The RTs and the accuracy data of  
46  
47 the CCE were analyzed using the factors body (body/object), synchrony  
48  
49 (synchronous/asynchronous), side (same side/different side) and congruency  
50  
51 (congruent/incongruent). We here focus mainly on the RT data rather than accuracy, as this  
52  
53 has been shown to be more sensitive for CCE analysis (Austen, Soto-Faraco, Enns, &  
54  
55 Kingstone, 2004; Shore, Barnes, & Spence, 2006; Spence, Pavani, & Driver, 2004). Fisher LSD  
56  
57  
58  
59  
60

1  
2  
3 (Last significant difference) test was used for post-hoc testing and the significance (alpha)  
4  
5 level used was  $p=0.05$ . Three participants had to be excluded from CCE analysis (one  
6  
7 because of chance level performance and two because of technical problems, e.g. less than  
8  
9 half of the trials were recorded in one condition). This resulted in a total  $N=14$  for the CCE  
10  
11 analysis. Trials with incorrect responses and trials in which participants failed to respond  
12  
13 within 1500 msec were discarded from reaction time (RT) analysis following the methods in  
14  
15 previous studies (Aspell et al., 2009; Spence et al., 2004). We also determined heart rate  
16  
17 variability from the ECG by calculating the average standard deviation of the average RR  
18  
19 intervals (SDANN) for each condition (Cowan, 1995) using repeated measures analyses of  
20  
21 variance (ANOVA) with factors body (body/object) and synchrony  
22  
23 (synchronous/asynchronous).

## 33 Results

### 34 *Self-identification*

35  
36  
37  
38  
39  
40 The mean responses to Q3 (“I felt as if the virtual body/object was my body”) are  
41  
42 shown in Figure 2A. The effects of seeing a body and synchronous stroking on the illusion  
43  
44 strength (average of responses to questions 1-3) was investigated using a  $2 \times 2 \times 2$  repeated  
45  
46 measures ANOVA. We found a significant main effect of body ( $N=17$ ,  $F_{1,16}=38.11$ ,  $p<0.001$ ,  
47  
48  $\eta_p^2=0.704$ ) and question type ( $N=17$ ,  $F_{1,16}=13.14$ ,  $p=0.02$ ,  $\eta_p^2=0.451$ ), as well as an interaction  
49  
50 between body and question type ( $N=17$ ,  $F_{1,16}=20.1$ ,  $p<0.001$ ,  $\eta_p^2=0.557$ ) and between body,  
51  
52 synchrony and question type ( $N=17$ ,  $F_{1,16}=4.36$ ,  $p=0.053$ ,  $\eta_p^2=0.214$ ). Further analysis using  
53  
54 planned-comparisons showed that the overall illusion was stronger during the BS as  
55  
56  
57  
58  
59  
60

1  
2  
3 compared to the BAS condition ( $p=0.01$ , one-tailed). No significance difference between the  
4  
5 average score of the control questions during the BS and BAS conditions nor for any type of  
6  
7 question during the object conditions could be found (all  $p>0.08$ , one-tailed).  
8  
9

10 Subsequent analysis focusing on mean responses to questions 1 through 3 (illusion  
11  
12 questions see Table 1), revealed that self-identification with the virtual body (question 3, see  
13  
14 Figure 2A) was stronger during the BS condition (mean=0.88) as compared to the BAS  
15  
16 condition (mean=-0.12;  $p=0.002$ , one-tailed) and the OS condition (mean=-2.29,  $p<0.001$ ,  
17  
18 one-tailed), as well as between the BAS and the OAS condition (mean=-2.41,  $p<0.001$ , one-  
19  
20 tailed). No significant difference was found between the OS and OAS condition ( $p=0.33$ , one-  
21  
22 tailed). These data, using cardio-visual conflict, and thus an intero-exteroceptive conflict, are  
23  
24 comparable to earlier data using purely exteroceptive, visuo-tactile, conflicts (7, 8, 13, 14).  
25  
26 Analysis of Q8 (“It seemed as if the flashing semi-transparent template was my heartbeat”)  
27  
28 revealed that participants were not aware of the experimental manipulation (mean ratings  
29  
30 across all conditions were negative and no significant difference could be observed between  
31  
32 the conditions; all  $p>0.07$ , one-tailed; see Figure 2B).  
33  
34  
35  
36  
37  
38  
39  
40

#### 41 *Self-location*

42  
43 Cardio-visual signals also altered self-location (as shown in Figure 2C): it was  
44  
45 modulated by cardio-visual synchrony, but only in the body conditions as predicted (based  
46  
47 on work using pure exteroceptive conflicts, i.e. greater change of self-location in the BS than  
48  
49 the BAS condition (Aspell et al., 2009; Lenggenhager et al., 2007)). Statistical analysis  
50  
51 revealed neither a significant main effect of body ( $N=17$ ,  $F_{1,16}=1.10$ ,  $p=0.31$ ,  $\eta_p^2=0.064$ ) nor of  
52  
53 synchrony ( $N=17$ ,  $F_{1,16}=0.38$ ,  $p=0.54$ ,  $\eta_p^2=0.023$ ), but did, crucially, reveal a significant two-  
54  
55 way interaction between body and synchrony ( $N=17$ ,  $F_{1,16}=8.93$ ,  $p<0.01$ ,  $\eta_p^2=0.358$ ). This was  
56  
57  
58  
59  
60

1  
2  
3 caused by a significant difference between the BS (mean =10.0cm+/-24.6cm) and the BAS  
4  
5 conditions (mean =-1.0cm+/-20.3 cm,  $p=0.02$ ). Further analysis revealed that self-location  
6  
7 differed from 0 only in the BS condition ( $p=0.05$ ), but not in the BAS condition  $p=0.41$ ). In  
8  
9 contrast, in the object conditions, self-location changes were generally smaller and did not  
10  
11 differ from 0 (all  $p>0.24$ ); they also did not differ between the OS (mean =-3.2cm+/-22.9cm)  
12  
13 and OAS conditions (mean =3.9cm+/-22.4cm,  $p=0.11$ ).  
14  
15  
16  
17  
18  
19

### 20 *Tactile perception*

21  
22 By measuring the magnitude of the visuo-tactile CCE during cardio-visual stimulation  
23  
24 we directly tested whether and how the cardio-visual signals altered the perception of  
25  
26 exteroceptive tactile cues that we applied to the body surface of our participants during the  
27  
28 illusion. Based on previous work showing that visuo-tactile stroking alters CCE magnitude  
29  
30 (Aspell et al., 2009; Zopf, Savage, & Williams, 2010) in conditions that induce changes in self-  
31  
32 identification and self-location, we here predicted that cardio-visual illumination should  
33  
34 induce similar changes. Because exteroceptive as well as interoceptive signals are involved in  
35  
36 bodily self-consciousness (as indicated by the present changes in self-identification and self-  
37  
38 location) we expected greater mislocalization of touch (as reflected in CCE magnitude)  
39  
40 towards the virtual body in the BS condition during cardio-visual stimulation. The critical test  
41  
42 is thus whether the visuo-tactile CCE varied as a function of cardio-visual synchrony.  
43  
44  
45  
46  
47  
48

49 Figure 2D plots this effect and shows that CCEs were larger during cardio-visual  
50  
51 synchrony. This effect was more pronounced if the vibration and the visual distractor were  
52  
53 on the same side than on the different side (three-way interaction between synchrony,  
54  
55 congruency and side;  $F_{1,13}=7.57$ ,  $p=0.02$ ,  $\eta_p^2=0.368$ ; see Figure S2A and B in the  
56  
57 Supplementary Material). Statistical analysis also revealed significant main effects of body  
58  
59  
60

1  
2  
3 (N=14,  $F_{1,13}=8.73$ ,  $p=0.01$ ,  $\eta_p^2=0.402$ ) and congruency ( $F_{1,13}=69.097$ ,  $p<0.001$ ,  $\eta_p^2=0.842$ ) as  
4  
5 well as a significant two-way interaction between side and congruency ( $F_{1,13}=40.75$ ,  $p<0.001$ ,  
6  
7  $\eta_p^2=0.758$ ). No significant interactions between body and synchrony ( $F_{1,13}=2.224$ ,  $p=0.16$ ),  
8  
9 body, synchrony, and congruency ( $F_{1,13}=0.827$ ,  $p=0.38$ ), body, synchrony, and side  
10  
11 ( $F_{1,13}=0.029$ ,  $p=0.87$ ), and no significant 4-way interaction between congruency, side,  
12  
13 synchrony, and body ( $F_{1,13}=0.0302$ ,  $p=0.87$ ) were found. For further discussion of CCE data  
14  
15 see Supplementary material and Figures S2A and B.  
16  
17

18  
19 As the magnitude of these CCE effects (RTs) due to cardio-visual illumination is  
20  
21 comparable to those observed for CCEs during visuo-tactile stroking (Aspell et al., 2009;  
22  
23 Spence et al., 2004; Zopf et al., 2010), this finding shows that a cardio-visual conflict  
24  
25 modulates how irrelevant visual signals interfere with the perception of tactile cues on one's  
26  
27 body surface. Further analysis revealed that these differences in touch perception (CCE) and  
28  
29 bodily self-consciousness (self-identification, self-location) are not related to more  
30  
31 elementary changes in heart physiology, such as differences in heart frequency and  
32  
33 variability: An ANOVA comparing the heart variability (SDANN) across conditions did not  
34  
35 reveal any significant main effects or interactions between BS ( $59\pm 49$  ms), BAS ( $44\pm 14$  ms),  
36  
37 OS ( $59\pm 58$  ms) and OAS ( $69\pm 85$  ms) (all  $p>0.33$ ); see figure S2C in the Supplementary  
38  
39 Material.

45  
46 Our finding of an alteration in the perception of tactile stimuli applied to one's body  
47  
48 surface while viewing a heartbeat-locked illumination of the virtual body suggests that  
49  
50 cardio-visual signals interfere with how tactile signals are integrated in the human brain. In  
51  
52 addition to their relevance for self-consciousness, the present behavioral data therefore also  
53  
54 extend data on viscerosomatic convergence (and in particular cardio-tactile convergence  
55  
56 that has previously been observed in spinal cord, brainstem, and thalamus) to cardiac signals  
57  
58  
59  
60

1  
2  
3 and their integration with exteroceptive signals at higher, most likely cortical levels of  
4  
5 processing (see Discussion).

## 11 12 **Discussion**

13  
14  
15  
16 The present study allows us to draw several conclusions. Our data are compatible  
17  
18 with evidence that has accumulated within two separate traditions in the neurosciences  
19  
20 pointing to the importance of exteroceptive *and* interoceptive systems for self-  
21  
22 consciousness. We show that signals from these systems – despite their anatomical,  
23  
24 physiological and functional differences – can be integrated. Since these integrated extero-  
25  
26 interoceptive (cardio-visual) signals are modulators of two crucial aspects of bodily self-  
27  
28 consciousness, we argue that the integration of signals from the inside and the outside of  
29  
30 the human body is a fundamental neurobiological process underlying self-consciousness.  
31  
32  
33  
34  
35

36 The present data demonstrate stronger self-identification and a greater shift in self-  
37  
38 location (as compared to the asynchronous condition) when an illuminating silhouette  
39  
40 surrounding a video image of the participant's own body flashed on and off synchronously  
41  
42 with the participant's heartbeat. This is the first time that an extero-interoceptive conflict  
43  
44 has been used to modulate bodily self-consciousness. Earlier studies used purely  
45  
46 exteroceptive (e.g. visuo-tactile) conflicts (Aspell et al., 2009; Lenggenhager et al., 2007; Zopf  
47  
48 et al., 2010). Our findings are compatible with earlier proposals that exteroceptive (Blanke et  
49  
50 al., 2004; Blanke & Metzinger, 2009) and interoceptive signals (A. D. Craig, 2002; Damasio,  
51  
52 2000; M. Tsakiris, Jimenez, & Costantini, 2011) are important for the representation of the  
53  
54 self in the brain.  
55  
56  
57  
58  
59  
60

1  
2  
3 It has been proposed that ownership of rubber hands and self-identification with  
4 virtual bodies (Botvinick & Cohen, 1998; Lenggenhager et al., 2007; Moseley, Gallace, &  
5  
6 virtual bodies (Botvinick & Cohen, 1998; Lenggenhager et al., 2007; Moseley, Gallace, &  
7  
8 Spence, 2011) is at least partly explained by the fact that tactile input (stroking) is inherently  
9  
10 self-specifying sensory information (Bermudez, 1995) because tactile stimuli *necessarily*  
11  
12 provide information about one's own body (whereas, e.g., visual and auditory signals do  
13  
14 not). Interoceptive (e.g. heartbeat) signals are also self-specifying sensory signals and in  
15  
16 addition, are 're-afferent' signals as they originate from the organism's visceral motor  
17  
18 control processes (Christoff, Cosmelli, Legrand, & Thompson, 2011). Given this, we argue  
19  
20 that when synchronous heartbeat timing information is presented to the participant, albeit  
21  
22 via an unusual route (vision), it serves to increase self-identification with the virtual body,  
23  
24 relative to the condition in which the visual information is asynchronous.  
25  
26  
27  
28  
29

30 It is notable that these cardio-visual effects on bodily self-consciousness are only  
31  
32 found when the flashing outline is viewed on a video image of the participant's body, not  
33  
34 when it is viewed on a control object. The cardio-visual synchrony effect is therefore not  
35  
36 sufficient on its own to cause changes in bodily self-consciousness: the visual object must  
37  
38 resemble a body. Similar findings were reported using visuo-tactile stimulation of whole  
39  
40 bodies (Lenggenhager et al., 2007) and hands (Haans, Ijsselsteijn, & de Kort, 2008; Manos  
41  
42 Tsakiris, Carpenter, James, & Fotopoulou, 2010; M Tsakiris & Haggard, 2005). Top-down  
43  
44 mechanisms, which refer to stored information about typical human body form, are likely to  
45  
46 be recruited in order for these illusions, including the present cardio-visual illusion one, to  
47  
48 occur: multisensory congruence alone is not sufficient (Makin, Holmes, & Ehrsson, 2008;  
49  
50 Manos Tsakiris et al., 2010).  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 By measuring the magnitude of visuo-tactile CCEs during cardio-visual stimulation we  
4  
5 show that cardio-visual signals also alter the perception of exteroceptive tactile cues: we  
6  
7 observed a greater mislocalization of touch during synchronous cardio-visual illumination.  
8  
9 These changes were of similar magnitude to those observed when the full body illusion was  
10  
11 induced using purely exteroceptive conflicts (Aspell et al., 2009). This alteration in the spatial  
12  
13 perception of tactile stimuli indicates that task irrelevant cardio-visual signals can selectively  
14  
15 alter tactile spatial perception (possibly via the integration of cardio-visual signals with  
16  
17 tactile signals). Concerning the underlying brain mechanisms, these CCE data suggest that  
18  
19 the interfering effects of the cardio-visual synchrony were conveyed to the somatosensory  
20  
21 system, thereby modulating tactile processing.  
22  
23  
24  
25  
26

27 Collectively, our data show that internal and external states of the body are  
28  
29 integrated and suggest that they converge within a common system representing the bodily  
30  
31 self. Viscero-somatic convergence has been described in the dorsal horn of the spinal cord,  
32  
33 the brain stem and the thalamus by revealing single neurons with tactile receptive fields that  
34  
35 also receive afferent cardiac input (Foreman et al., 1984; Takahashi & Yokota, 1983). Such  
36  
37 convergence has been proposed to account for the referred location of visceral sensations,  
38  
39 most notoriously of heart pain (angina pectoris) that may be felt on the trunk, face, and  
40  
41 upper extremities (referred pain (Ruch, 1965)). Thus, afferent signals from the viscera  
42  
43 converge with somatosensory afferents from specific body parts (Foreman et al., 1984; Holzl,  
44  
45 Moltner, & Neidig, 1998). Our data shows that not only viscerosomatic but also viscerovisual  
46  
47 information can be integrated. Based on the anatomy of the visceral and visual  
48  
49 pathways we suggest that the present cardio-visual integration is supported by cortical (or  
50  
51 thalamic) structures rather than other subthalamic or spinal structures. Cortical convergence  
52  
53 is further supported by our finding that illusory self-identification and self-location due to  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 cardio-visual synchrony were only observed when participants viewed a body, but not when  
4  
5 they viewed an object. Since awareness of cardiac signals has been shown to rely on  
6  
7 somatosensory signals conveyed through parietal cortex (e.g. chest wall; (Khalsa et al.,  
8  
9 2009)), and since posterior parietal areas 5 and 7 have been shown to contain bimodal  
10  
11 neurons responding to visual and tactile input (Iriki, Tanaka, & Iwamura, 1996; Mountcastle,  
12  
13 Lynch, Georgopoulos, Sakata, & Acuna, 1975), we suggest that cardio-visual signals might be  
14  
15 integrated in posterior parietal cortex and are thus able to modulate bodily self-  
16  
17 consciousness and somatosensory processing.  
18  
19  
20  
21  
22

23 The observed behavioral changes in somatosensory cortex may have also occurred as  
24  
25 a consequence of signals arriving from different brain regions such as the insula or the  
26  
27 parietal cortex (e.g. SII). The insula (Khalsa et al., 2009) has been shown to be recruited  
28  
29 during the perception of cardiac signals. Cardio-visual signals could thus also have been  
30  
31 integrated in the insula first and these integrated signals could then have modulated tactile  
32  
33 processing and bodily self-consciousness. The insula is a key area for interoception, is  
34  
35 important for heartbeat awareness (Critchley et al., 2004), and has been proposed to be  
36  
37 crucial for subjective bodily feelings (A. Craig, 2010; A. D. Craig, 2002). It is a highly  
38  
39 multisensory brain region that is also activated by visual, tactile, and auditory cues (Kondo &  
40  
41 Kashino, 2007; Kranczioch, Debener, Schwarzbach, Goebel, & Engel, 2005; Pressnitzer &  
42  
43 Hupe, 2006). Both the posterior parietal cortex and the insula have been implicated in a  
44  
45 number of studies on self-attribution of a fake or virtual hand (Press, Heyes, Haggard, &  
46  
47 Eimer, 2008), (Ehrsson, Spence, & Passingham, 2004; Farrer & Frith, 2002; M Tsakiris, Hesse,  
48  
49 Boy, Haggard, & Fink, 2007).  
50  
51

1  
2  
3 In conclusion, the present data on changes in self-identification, self-location and  
4 tactile perception suggest that neural mechanisms for detecting correlations between the  
5 timing of a flashing visual stimulus and the heartbeat are highly sensitive and are powerful  
6 modulators of bodily self-consciousness. The brain's detection of correlations among  
7 multisensory signals is an important basis for distinguishing self from non-self (Botvinick &  
8 Cohen, 1998; Rochat & Striano, 2000; van den Bos & Jeannerod, 2002). The current  
9 heartbeat illumination paradigm brought interoceptive cues to the 'outside' and allowed us  
10 to induce a number of different fine-grained behavioral changes. Given that our data show  
11 that exteroceptive and interoceptive signals are combined and that they are potent  
12 modulators of bodily self-consciousness, we propose that signals from the inside and the  
13 outside of the human body form an integrated cortical system for bodily self-consciousness.

### 34 **Figure legends**

35  
36  
37 **Figure 1. Setup.** Participants (a) stood with their backs facing a video camera placed 200 cm  
38 behind them (b). An electrocardiogram was recorded (a) and R-Peaks were detected in real-  
39 time (c), triggering a flashing silhouette outlining the participant's body (virtual body) (d).  
40 The video, showing the virtual body was projected in real time onto a head mounted display  
41 (HMD) (body condition). It appeared visually that the virtual body was standing 200 cm in  
42 front of the participant (e). After each block participants were passively displaced 150 cm  
43 backwards to the camera and instructed to walk back to the original position. See also  
44 Supplementary Figure S1 and Movie S1.

1  
2  
3 **Figure 2. a.** Self-identification (Q3: 'I felt as if the body/object was my body') significantly  
4 differed between the body synchronous condition (BS; mean=0.88) and the body  
5 asynchronous condition (BAS; mean=-0.12); and object synchronous condition (OS; mean=-  
6 2.29). Importantly, no difference between the object synchronous (OS; mean=-2.29) and  
7 object asynchronous condition (OAS; mean = -2.41) was found (N=17). White bars represent  
8 synchronous conditions, grey bars represent asynchronous conditions. Error bars indicate  
9 standard errors of the mean  
10  
11 **b.** Heartbeat awareness was not significantly different between the four conditions (Q8: 'It  
12 seemed as if the flashing semi-transparent template was my heartbeat').  
13  
14 **c.** Self-location was modulated by cardio-visual synchrony in the body condition only, with a  
15 greater change of self-location towards the virtual body in BS than in BAS. No significant  
16 difference was found between the OS and OAS (N=17).  
17  
18 **d. CCE** The CCE (N=14) was larger during cardio-visual synchrony and had greater magnitude  
19 when the vibration and the visual distractor were on the same side (three-way interaction  
20 between synchrony, congruency and side;  $F_{1,13} = 7.57$ ,  $p = 0.02$ ).. See also Figure S2 in  
21 Supplementary Material.

During the experiment there were times when :
1. It seemed as if I was feeling the vibration where I saw the virtual body/object.
2. It seemed as though I was in two places at the same time.
3. I felt as if the virtual body/object was my body.
4. It seemed as if the vibration I was feeling came from somewhere between my own body and the virtual body/object.
5. It felt as if my (real) body was drifting towards the front (towards the virtual body/object).
6. It appeared (visually) as if the virtual body/object was drifting backwards (towards my body).
7. It seemed as if I might have more than one body.
8. It seemed as if the flashing semi-transparent template was my heartbeat.
9. I felt as if my heart was in the virtual body/object.
10. It seemed as if I had two hearts.
11. It seemed as if I was feeling my heartbeat where I saw the semi-transparent template flashing.
